We pay particular attention to the cell signaling pathways, kinases, long non-coding RNAs (lncRNAs), chromatin remodeling and DNA repair machineries that may be involved in the regulation of key genes in the process of cell dedifferentiation and cancer.

Chromatin is a fundamental component in the network of controls that regulates gene expression. Many human diseases have been linked to disruption of these control processes by genetic or environmental factors, and unravelling the mechanisms by which they operate is one of the most exciting and rapidly developing areas of modern biology.

In recent years, with the technology and bioinformatics analysis development, the molecular mechanism of ZNF143-mediated gene transcriptional regulation has been largely exploited. Chromatin looping between promoters and distal regulatory elements depends on DNA binding by ZNF143 and other partners.

In humans, more than 30% of protein coding genes have antisense transcripts and some of these are important regulators of chromatin architecture and gene regulation [156,157]. lncRNAs are defined as transcripts larger than 200 nucleotides and are in a separate category from other small RNAs such as microRNAs, small nucleolar RNAs (snoRNAs), and small interfering RNAs (siRNAs). lncRNAs are defined into 5 groups based on their relative position to coding genes. These categories are intergenic ...

We focus our research on the control of gene expression in human cells by chromatin organization, components and modifications, with a focus on the linker histone. The linker histone in mammals, participating in nucleosome spacing and higher-order chromatin structure, is a family of different histone H1 subtypes, including 7 somatic variants.

Chromatin is a complex of DNA and protein found in eukaryotic cells. Its primary function is packaging long DNA molecules into more compact, denser structures. This prevents the strands from becoming tangled and also plays

In a paper published in the journal Nature, researchers from the laboratory of Frederick Alt, PhD, of the Program in Cellular and Molecular Medicine (PCMM) at Boston Children's Hospital reveal insights into a new mechanism of chromatin regulation – changing the configuration of our DNA and its packaging – and how that influences antibody formation and gene regulation in general.

Regulation of chromatin and gene expression by metabolic enzymes and metabolites Metabolism and gene expression, which are two fundamental biological processes that are essential to all living organisms, reciprocally regulate each other to maintain homeostasis and regulate cell growth, survival and differentiation.

Chromatin structure is regulated by DNA methylation, histone modifications, and chromatin remodeling. Chromatin-remodeling factors are molecular motors that use the energy from ATP hydrolysis to slide nucleosomes along or off DNA, thereby regulating the accessibility of the underlying DNA to various nuclear factors (Narlikar et al., 2013).

Chromatin remodeling complexes (CRCs) use ATP hydrolysis to maintain correct expression profiles, chromatin stability, and inherited epigenetic states. More than 20 CRCs have been described to date, which encompass four large families defined by their ATPase subunits. These complexes and their subunits are conserved from yeast to humans through evolution.

Chromatin structure and gene regulation. The organisation of chromatin within the nucleus profoundly influences gene expression. We study how the actively transcribed genome is organised in the nucleus, how different chromatin components contribute to gene regulation and how variations in these components result in disease.
